The program might look like this:

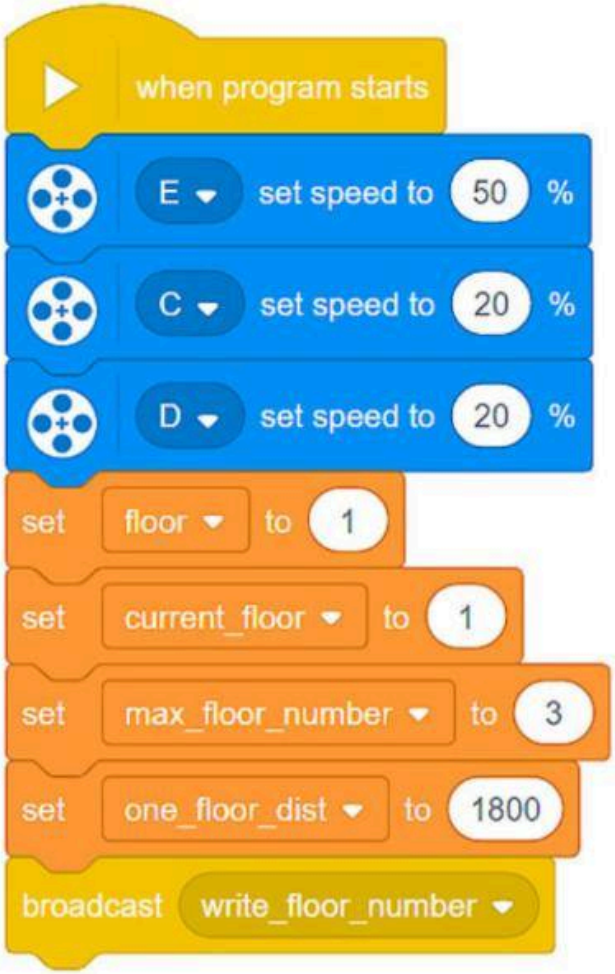

Algorithm of the program:

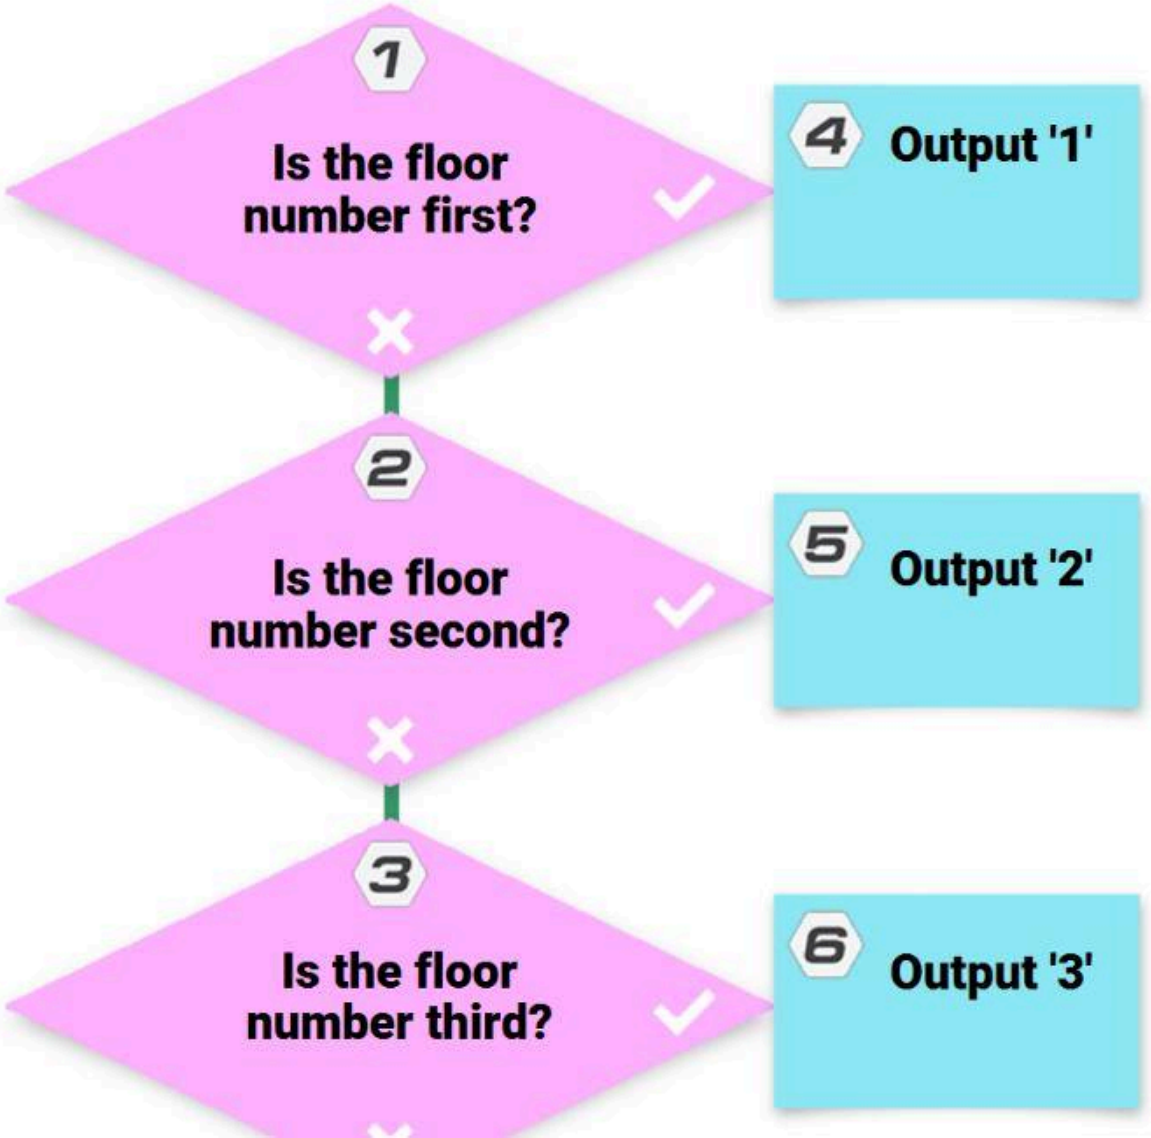

A program that is executed immediately after startup and sets the initial values of variables may look like this:

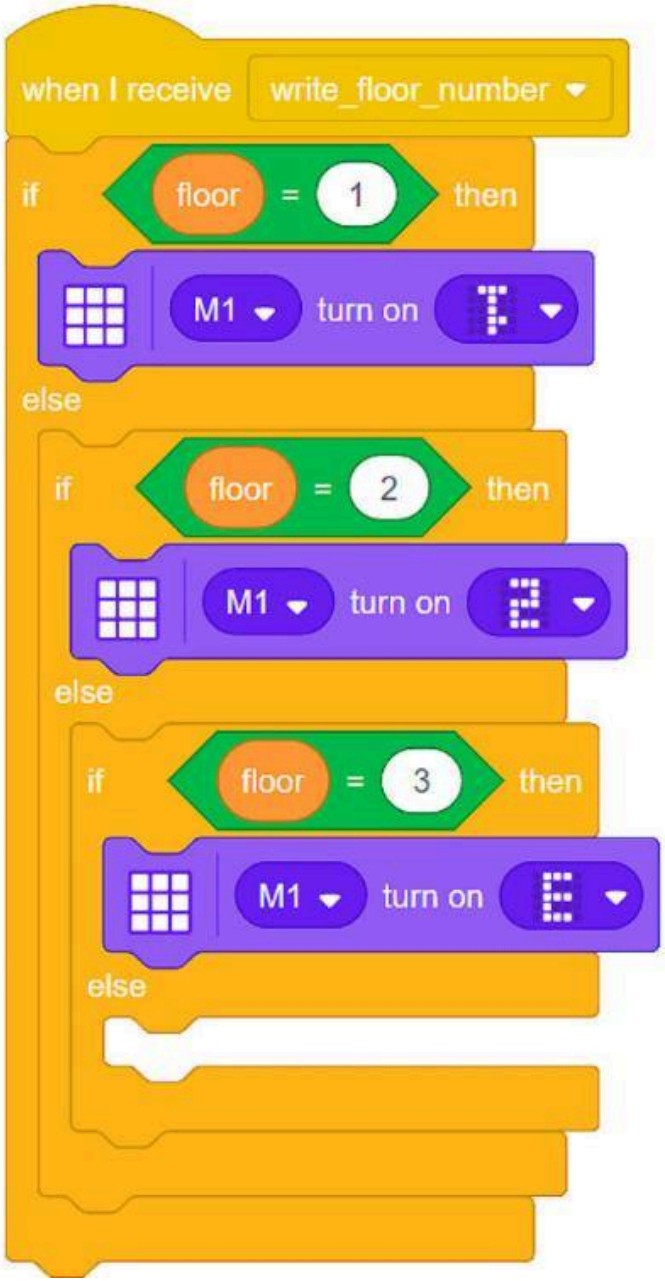

Changeable 'floor' contains the number of the floor the user wants to go to.
Changeable 'current_floor' contains the number of the floor on which the elevator car is located.
Changeable 'max_floor_number' is the number of the highest floor to which the elevator should move.

Note! With this initial value of the 'current_floor' variable, the program should be run when the elevator car is on the first floor.

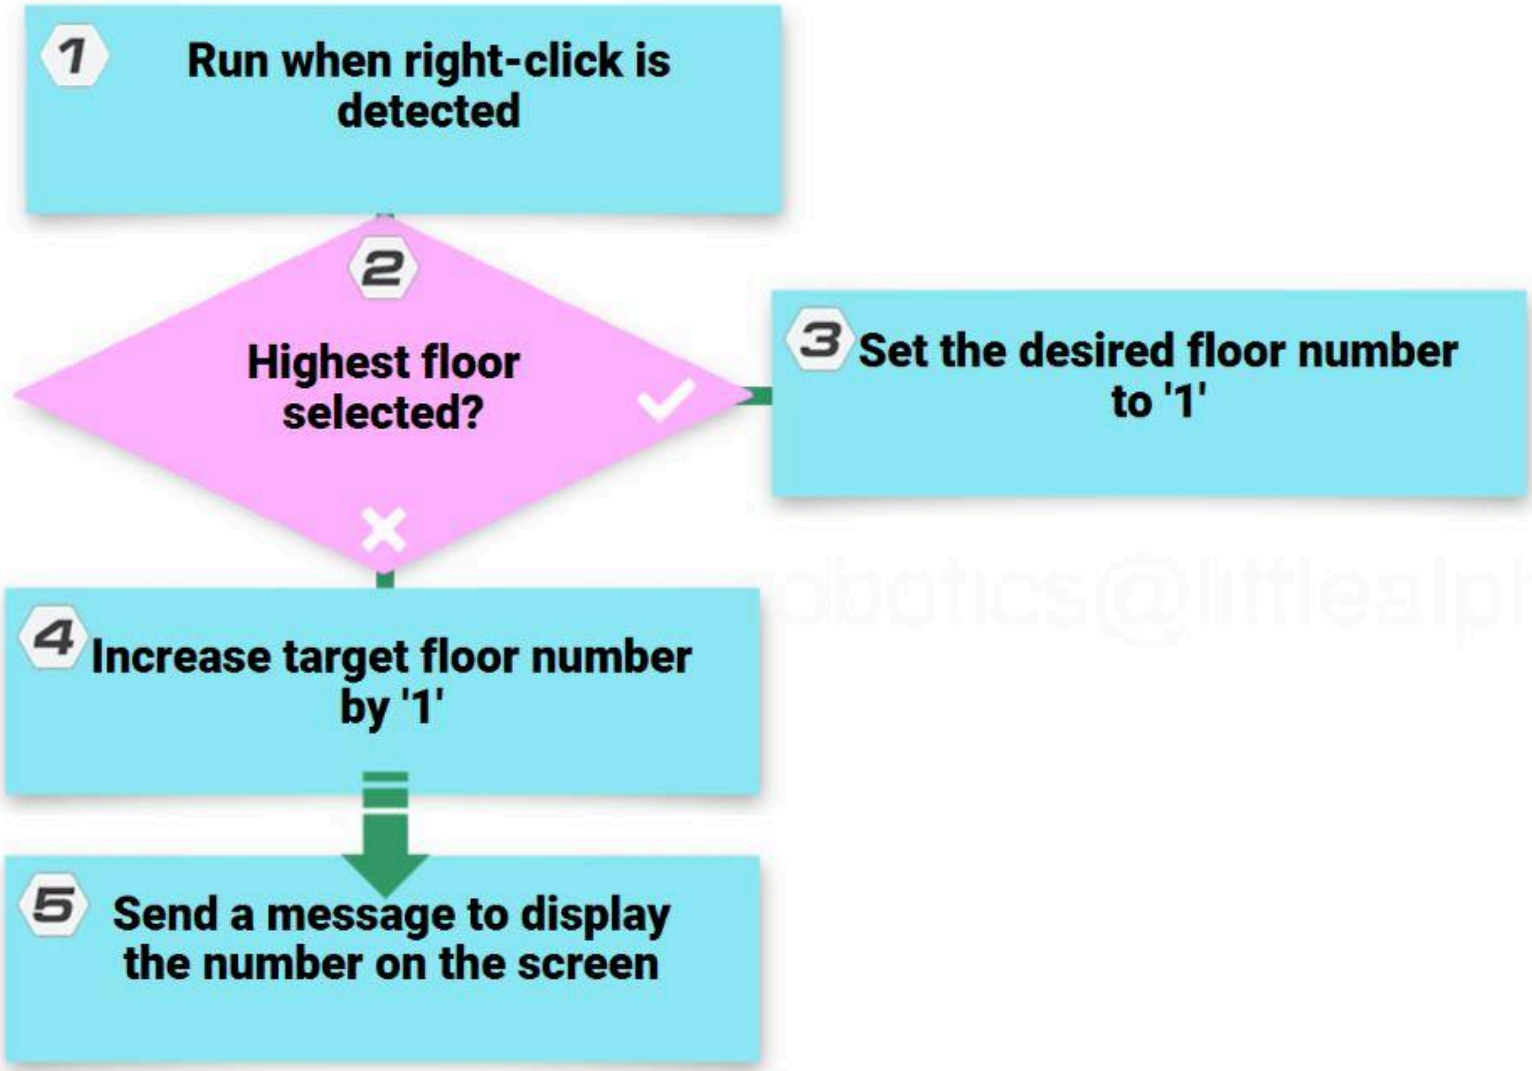

The floor number should be displayed upside-down. To do this, you can use the image display mode:

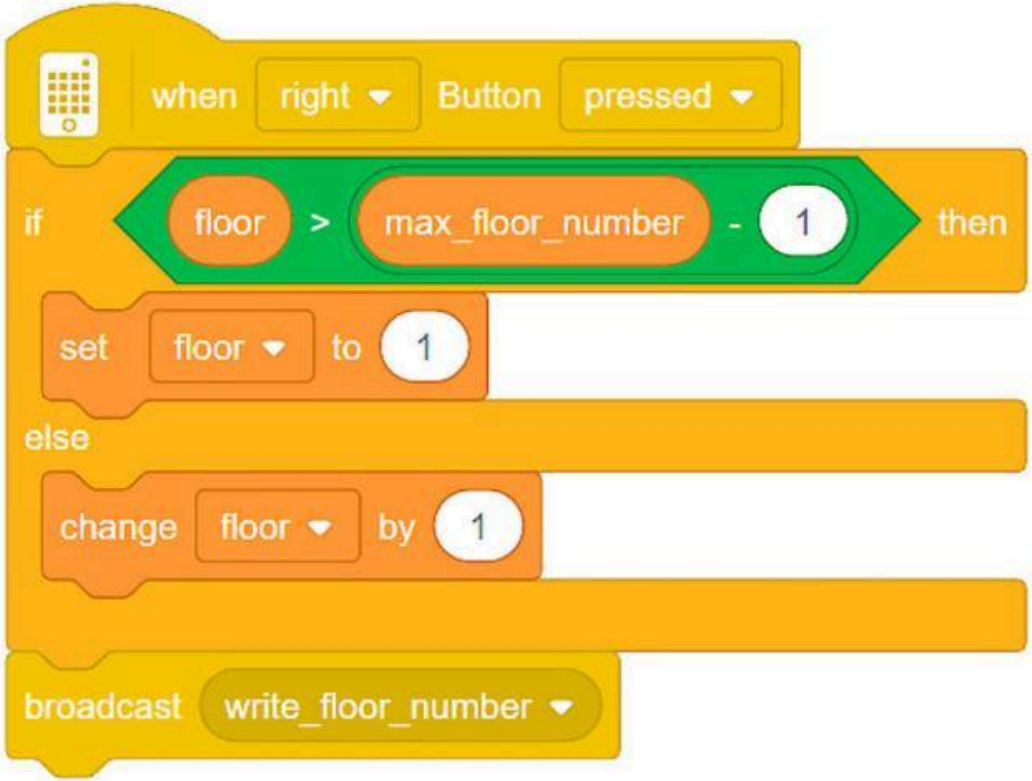

The program that displays the floor number on the screen might look like this:

The processing algorithm for pressing the right button of a block can be as follows:

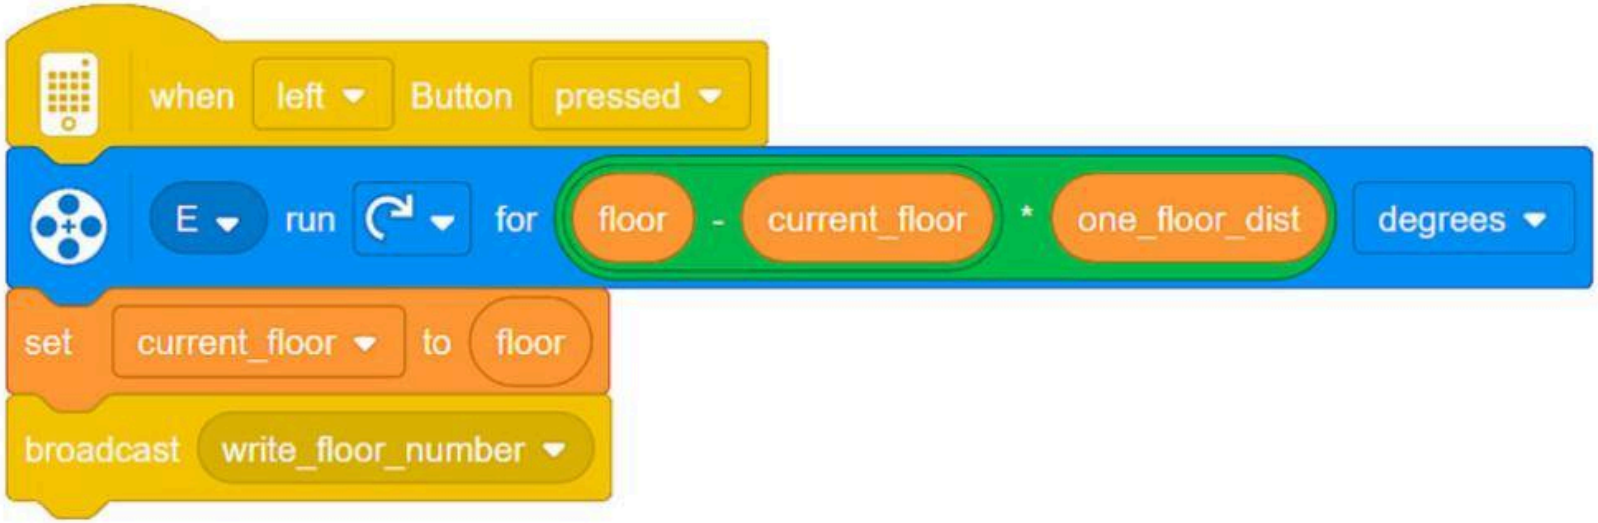

The program for choosing a floor number might look like this:

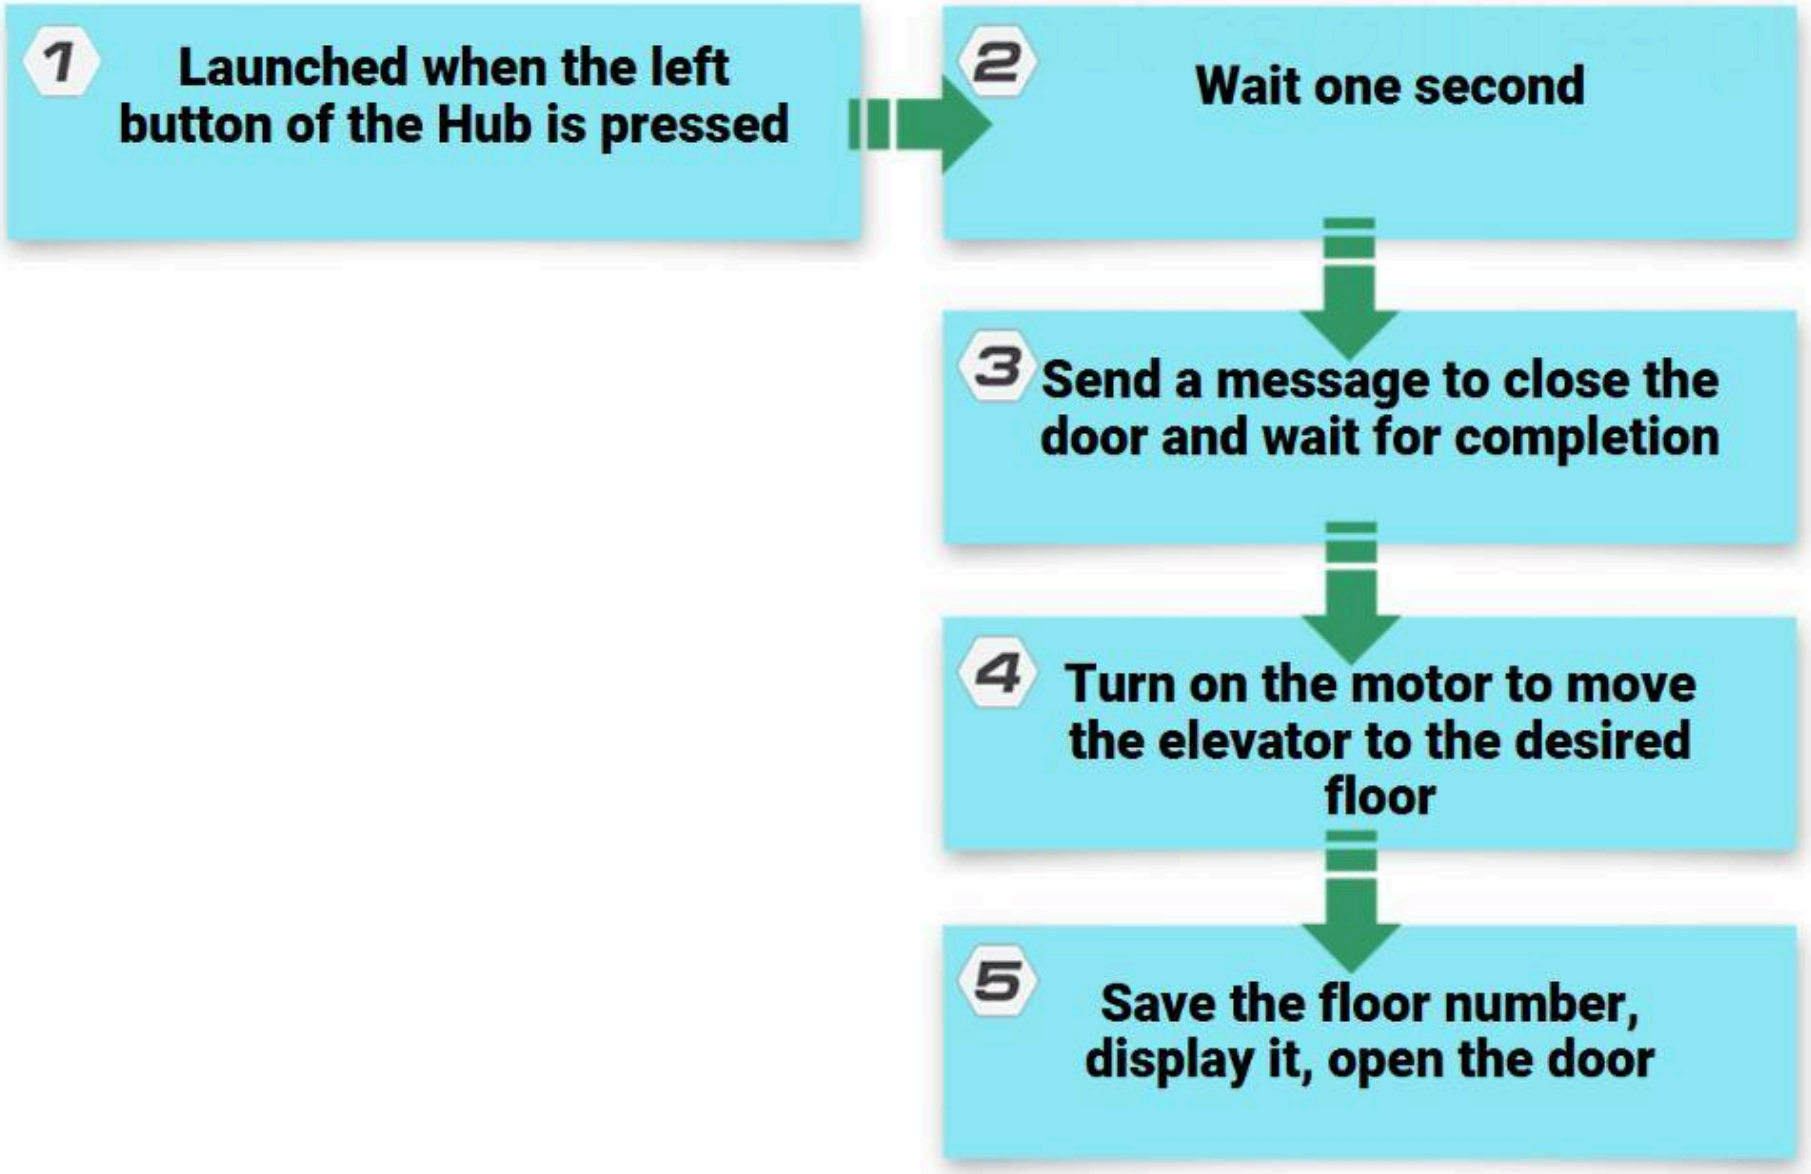

The floor number the user wants to travel to is stored in the 'floor' variable. Please note that if the number of the desired floor is greater than the number of floors in the house, then the number of the desired floor becomes equal to 1. This way you can select the floor number. The number of floors in the house is stored in the 'max_floor_number' variable.

The program for starting the elevator may look like this:

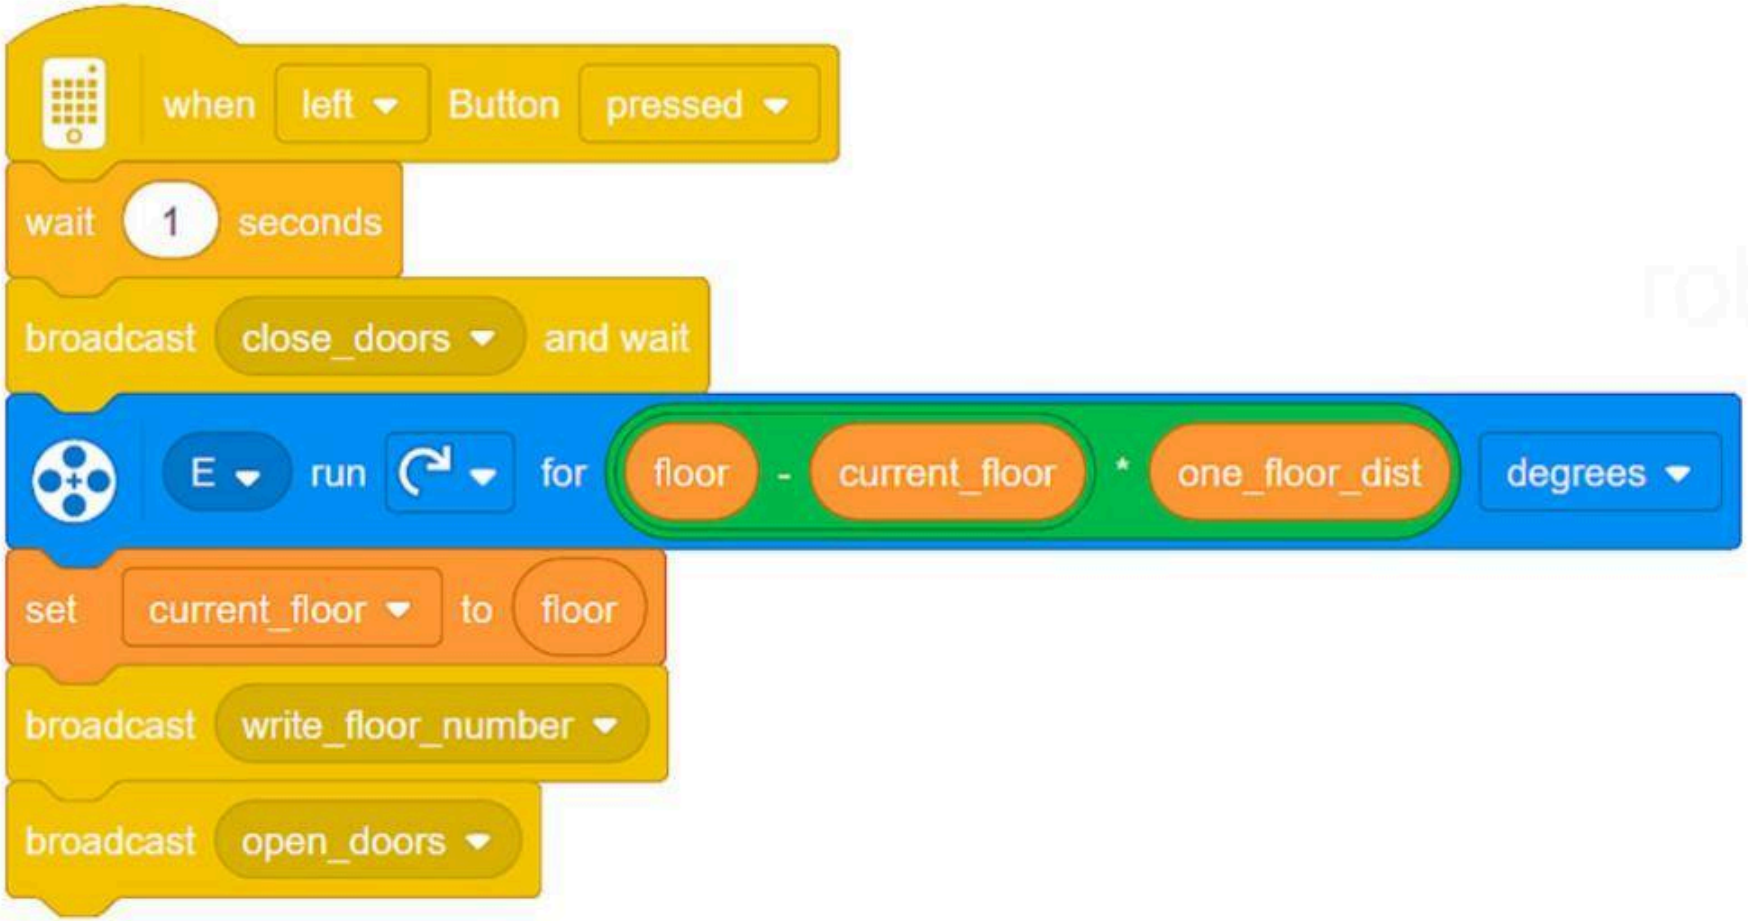

In the first task, you tested and figured out the number of winch revolutions required to move the elevator one floor. By multiplying it by the difference between the number of the current and the desired floor, you can get the number of revolutions required to move to the desired floor. After the end of the movement, the number of the current floor becomes equal to the number of the desired one.

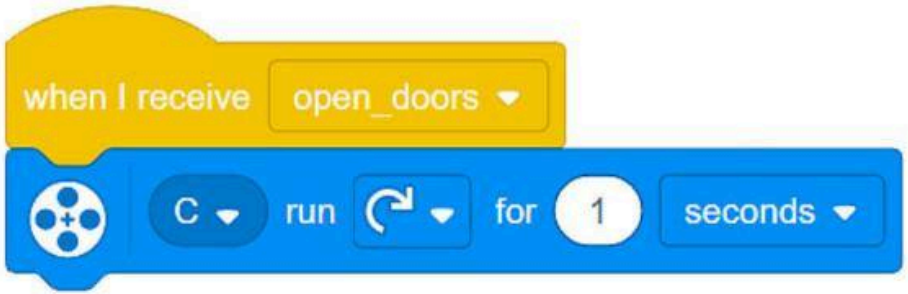

The task execution algorithm can be as follows:

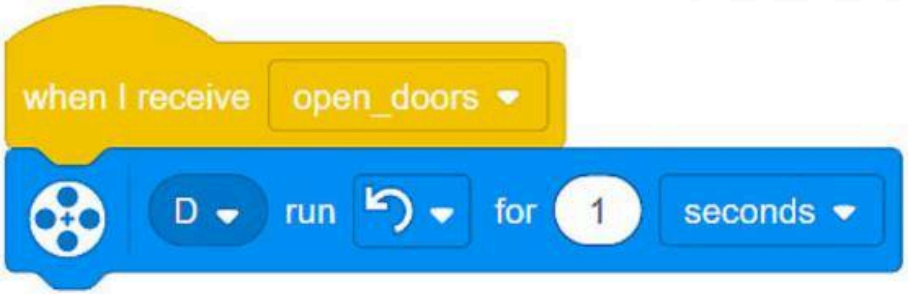

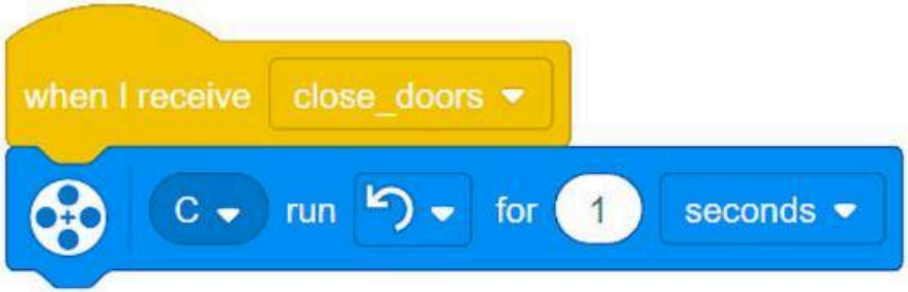

Modify the elevator start application as follows:

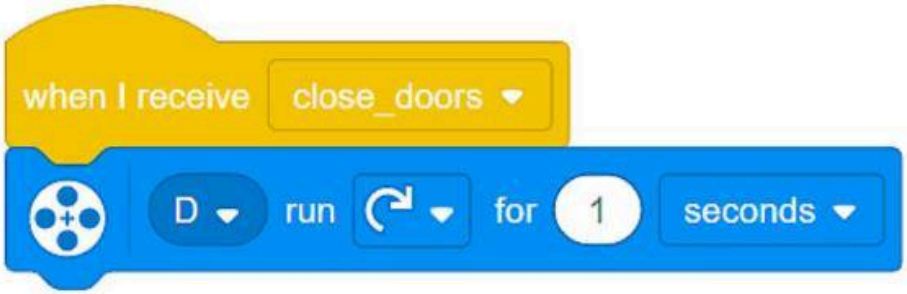

Programs that open and close doors may look like this:

You also need to slightly modify the first program so that the elevator door opens when it starts:
